# IDENTIFYING EFFICIENT PUMP COMBINATIONS IN WATER DISTRIBUTION NETWORKS 

Levent DORUK, Nuri MERZI ${ }^{1}$<br>IWRA Member, Middle East Technical University, Civil Engineering Department, 06531<br>Ankara, Turkey

#### Abstract

SUMMARY Energy costs regarding pumping discharge lines constitute the most important item in the budget of the water utilities in relation to municipal water distribution networks. Selection of the efficient pump combination during operation might reduce energy costs. For the correct choice of pump selection, characteristics of the transmission lines and network pipes, actual pump performance curves, daily demand curve should be known for defining the task. The definition of the task denotes the increase of the storage tank of the system from a given level to a certain level during a specific period of the day. Different examples were worked out using SCADA data using geographic information systems (GIS). It was found out that efficient pump combinations reduces energy costs considerably. The magnitude of the savings varies $5 \%-10 \%$ depending on the case studied.

## INTRODUCTION

Energy costs regarding pumping discharge lines constitute the most important item in the budget of the water utilities in relation to municipal water distribution networks. Selection of the efficient pump combination during operation might reduce energy costs. For the correct choice of pump selection, characteristics of the transmission lines and network pipes, actual pump performance curves, daily demand curve should be known for the defined task. The definition of the task denotes the increase of the storage tank of the system from a given level to a certain level during a specific period of the day. Basic pump performance curves are head-discharge and efficiency curves. There are various algorithms in the literaure for the efficient pump selection regarding the determination of the operation policies; this study puts in practice Ormsbee and Walski (1989) and Chase and Ormsbee (1993) algorithms using geographic information systems (GIS) concerning real time applications of a twopressure zone region with multi storage tanks. The case study area was located within the water distribution network of Ankara, Turkey.

## METHODOLOGY

First Step. The required amount of water, $\mathrm{Q}_{\mathrm{req}}$, during pumping period, T , is determined based on the defined the task. It consists of basically two parts; one is the amount of water, increasing the level of the storage $\operatorname{tank}(\mathrm{s})$ from the initial level of $\mathrm{H}_{\mathrm{i}}$ to the final level of $\mathrm{H}_{\mathrm{f}}$, the other is the required water, satisfying the consumers' demands during T :

$$
\mathrm{Q}_{\mathrm{req}}=\mathrm{Q}_{\mathrm{use}}+(1 / \mathrm{T}) * \sum_{\mathbf{1}}^{\mathbf{N}} \mathrm{A}_{\mathrm{tank}}(\mathrm{k}) *\left[\mathrm{H}_{\mathrm{f}}(\mathrm{k})-\mathrm{H}_{\mathrm{i}}(\mathrm{k})\right]
$$

where N , is the number of tanks; k , is the pump in operation; $\mathrm{A}_{\text {tank }}$, is the surface area of the tank; T , is the pumping period; $\mathrm{Q}_{\text {use }}$ is the flow of water used by the consumers during T. Both recent demand curve of the pressure zone and actual SCADA readings were employed concerning the determination of $\mathrm{Q}_{\text {use }}$.
Second Step. The number of all the pump combinations are determined; for each combination the network is solved by using a hydraulic network solver where each tank level
is taken as equal to the initial level. The solution of each pump combination provides pump discharge values either above or below the the required discharge $\mathrm{Q}_{\text {req. }}$. At $\mathrm{a}_{\mathrm{a}}$ given combination, pumps discharging above $\mathrm{Q}_{\text {req }}$ are called all together, $\mathrm{Q}_{\mathrm{a}}\left(\mathrm{Q}_{\mathrm{a}}>\mathrm{Q}_{\mathrm{req}}\right)$ whereas pumps discharging below $\mathrm{Q}_{\mathrm{req}}$ are called all together,
$\mathrm{Q}_{\mathrm{b}}\left(\mathrm{Q}_{\mathrm{b}}<\mathrm{Q}_{\mathrm{req}}\right)$. In order to accomplish the task within the given period, the pumps discharging all together $\mathrm{Q}_{\mathrm{a}}$, should run shorter than the pumps discharging all
together $\mathrm{Q}_{\mathrm{b}}$.
Third Step. Both $Q_{a}$ and $Q_{b}$ vary as a function of time because of the varying tank levels. In order to take into account this fact an iterative method is applied; average values of $Q_{a}$ and $Q_{b}$ are calculated succesively based on different durations of $f_{a} * T$ and $f_{b} * T$ where $f_{a}$ and $f_{b}$ add to unity using extended period simulation option of the hydraulic network solver. At a particular combination of $f_{a}$ and $f_{b}, Q_{\text {req }}$ is satisfied:

$$
\begin{equation*}
\mathrm{Q}_{\mathrm{req}}=\mathrm{f}_{\mathrm{a}} * \overline{\mathrm{Q}}_{\mathrm{a}}+\mathrm{f}_{\mathrm{b}} * \overline{\mathrm{Q}}_{\mathrm{b}} \tag{2}
\end{equation*}
$$

Fourth Step. The energy required for satisfying $\mathrm{Q}_{\mathrm{req}}$, is determined based on the operation of pumps discharging both above and below $\mathrm{Q}_{\mathrm{req}}$ :

$$
\begin{align*}
& \mathrm{P}=\left(\gamma * \mathrm{Q}_{\mathrm{p}} * \mathrm{H}_{\mathrm{p}}\right) / \mathrm{e}  \tag{3}\\
& \mathrm{E}=\sum_{\mathbf{1}}^{\mathrm{T} / \Delta \mathrm{t}} \mathrm{P}_{\mathrm{i}} * \Delta \mathrm{t}
\end{align*}
$$

where $P$ is power, $\gamma$ is specific weight of water, $Q_{p}$ is water discharged through the pump, $H_{p}$ is head produced by the pump, e is the efficiency of the operating point of the related pump, $E$ is the energy required, $\Delta t$ is the period of the considered operation during extended period simulation.
Fifth Step. The cost for each alternative will then be calculated by using unit price of electricity. The lowest cost will be recommended as the most efficient pump combination. For each alternative, each pump operation both above and below $\mathrm{Q}_{\text {req }}$ will be taken into account by evaluating each time increment during operation.
The network was modeled using the system characteristics gathered from the water utility of Ankara. The methodology described above has been coded into a computer program which combines all the network data implemented in a GIS environment, SCADA recordings, a hydraulic network solver and the above mentioned algorithm.

## CASE STUDY

The already defined algorithm was applied to a two- pressure zone region with multi storage tanks; the case study area was located within the water distribution network of Ankara, Turkey. The pressure zones N7 and N8 were located at the northern part of Ankara; the total population is approximately 85000 ; these pressure zones are the most upstream pressure zones on the North transmission line of Ankara. There are three parallely connected pumps at each of the pumping stations. Each storage tank has a capacity of $5000 \mathrm{~m}^{3}$. SCADA recordings contain the discharge data of the water pumped to the pressure zone(s).

## One Pressure Zone

First studied case dates from 21-22 July 1997. The defined task is to increase the tank level from 1155.09 m to 1157.38 m during 16 hours between 17:00 on July and 09:00 on July 22 (N8 pressur zone); the average water demand was equal to $37.08 \mathrm{lt} / \mathrm{s}$. According to the defined task, following result was obtained (Table 1). The combination numbered " 6 " was used in actual application by the operator; however, the combination numbered " 20 " was indicated by the proposed methodology as the least cost alternative which allows $4.53 \%$ saving.

Table 1. Result of the Case Study on 21-22 July 1997

In addition to the real case example, a synthetic scenario was generated: the pressure at the suction side was assumed to be decreased by ten meters. The defined task is to increase the tank level from 1154.00 m to 1155.00 during seven hours between 20:00 and 03:00 where the average water demand is equal to $15 \mathrm{lt} / \mathrm{sec}$. According to the defined task, following result was obtained (Table 2). The least cost combination is numbered as " 18 ". Compared with other combinations, it is noted that at most $14.7 \%$ and at least $1 \%$ saving could be achieved.

## Multiple Zone

On Figure 1, a multiple zone with three separate zones is given. According to multiple zone model, first the pump combinations of zone $A$ and zone $B$ have to be identified in order to determine the discharge required at zone C for the predefined task period. Therefore, if a task were defined for zone C, also zone A and zone B have to be solved by the computer program in advance separately for the time period described at the task of zone C . While solving the upper zones, no new tasks were defined related with tank elevations but in fact required demand is taken into consideration for these zones regarding the duration of the time interval defined for zone C .

Figure 5.1. Multiple zone configuration

Finding the required pump discharge for P1 and P2 pump stations, the combined discharge file is then created in order to use it for zone C's input file. Demand values for upper zones have to be attached to the nodes, which connects the zone C to other zones. Unlike the single zone case, this model will include all pumps at the various pumping stations. Using current pump status at the other pump stations, simulation will be conducted to determine the hydraulic impact of placing the proposed pump groups into service. In the multi zones study, the subject of this study was progressed through N7 zone, which is connected to N 8 sub pressure zones. In this part of the study, studied system became more complicated by including other storage tanks and pump stations at N 7 zone.

The real case example dates from 23 May 2001. The defined task is to increase the tank level at N 7 zone from 1113.15 m to 1114.58 m during 2.5 hours between $00: 30$ and $03: 00$, where the average water demand is equal to $42.02 \mathrm{lt} / \mathrm{s}$.

According to the suggested method for multi zone systems, first N8 zone, which is the upper zone of N7, was solved without defining a particular task for this zone but considering the required demand in the zone for the duration of the time interval defined for zone N7. First of all, the upper zone, N 8 was solved (Table 3).

Table 3. Result of the Case Study on 23 May for N8 zone

At the beginning of the time period at $00: 30$ the tank level at T 53 was 1155.41 m . Considering both the ending tank levels and the total costs of the combinations second one was selected, because its ending level is slightly higher and near to the beginning level and its cost is relatively lower when compared to the others. When the combination " 3 ", which was used in real application by the operator, was compared with this combination " 2 ", it was noticed that approximately $14.73 \%$ saving could be achieved. Second, the obtained pump discharge values from the selected combination were attached to the link node at N7 zone, which connects N8 zone to the N7 zone. The demand values for that node are presented on Table 4. Then, N7 zone was solved according to the pre-described task with the first option of the computer program considering required demand and the tank levels. According to this option, the following result was obtained for N 7 zone (Table 5).

Table 4. Demand Values for the Connection Node at N7 zone on 23 May

| Time | Demand (lit/s) |
| :---: | :---: |
| $00: 30: 00$ | 0 |
| $01: 00: 00$ | 0 |
| $01: 30: 00$ | 0 |
| $02: 00: 00$ | 39.38 |
| $02: 30: 00$ | 39.35 |

When the costs associated with the combinations were examined in the output on Table 5, it was seen that the combination " 11 " was having the least cost. When the combination " 21 " which was used in real application by the operator, was compared with the combination " 11 ", it was seen that approximately $3.66 \%$ saving could be achieved. In overall $4.35 \%$ cost saving was achieved for this particular case.

## CONCLUSIONS

Different examples were worked out using SCADA data concerning both on past data and real time applications using geographic information systems (GIS). It was found out that efficient pump combinations reduces energy costs considerably. The magnitude of the savings varies $5 \%-10 \%$ depending on the case studied. The
reduction increases if the pressure on the suction side differes from the design pressure. A procedure was offered also for using the proposed methodology to be handled by system operators.
